Keywords: solar cells, nanoparticles, absorption, transparency

In the past decade, intensive studies have been carried out on the dye-sensitized solar cells (DSSC) because of their high energy conversion efficiency [1]. An efficiency of 10.4\% was obtained using a black dye [2] as sensitizer and recently higher efficiency of 11.04\% was achieved with modified redox electrolyte [3]. The nanocrystalline mesoporous TiO\textsubscript{2} film is a basic component of DSSC. The fabrication procedure of TiO\textsubscript{2} photoelectrodes includes a synthesis of nanoparticles of a certain size and a crystal structure, deposition of the nanoporous films on the transparent conductive substrates, and activation of the nanoparticles for the dye absorption. Since the performance of the mesoporous solar cells is strongly linked with the interconnection of nanoparticles and their surface activity [4-6], organic binders are usually added to the concentric TiO\textsubscript{2} gel for increasing the viscosity of the colloid and the interconnection of nanoparticles in the films, and the surface treatment was applied for the activation of nanoparticles. However, the viscosity can be increased not only by adding the organic binders but also by changing the pH of the colloid [7]. The slurry is the most viscous at the point of zero charge (PZC) of nanoparticles [7] and the PZC for anatase TiO\textsubscript{2} is at pH 6.2 [8]. The TiO\textsubscript{2} nanoporous films for dye-sensitized solar cells (DSSC) have recently been fabricated at low temperatures by adding the basic ammonia to the binder-free acidic gel [9]. However, the authors achieved the maximum pH 3.6 of the TiO\textsubscript{2} slurry, which is still so far from the charge of the PZC of TiO\textsubscript{2} anatase.

Here we report on the new simplified fabrication technique of highly activated nanocrystalline TiO\textsubscript{2} photoelectrode consisting of discharged TiO\textsubscript{2} nanoparticles. The ammonia hydroxide was used for discharging TiO\textsubscript{2} nanoparticles to reach pH 5 of TiO\textsubscript{2} colloid. AFM and XRD analysis reveals high porosity of the TiO\textsubscript{2} films and the anatase crystal structure of the TiO\textsubscript{2} nanoparticles. The analysis of absorption spectra shows the high transparency of TiO\textsubscript{2} multilayer
photoelectrodes. A conversion efficiency of 9.5 % was achieved on the solar cells based on N719 absorbed TiO2 photoelectrodes by simulating AM 1.5 solar light (100 mW/cm²).

**Experimental:** The photoelectrodes were compositied from the transparent conductive SnO2:F(FTO) films deposited on glass which was covered with the nanocrystalline TiO2 dense thin film followed the nanoporous TiO2 thick film.

**TiO2 nanoparticles synthesis:** The amorphous TiO2 nanoparticles were synthesized by the sol gel method using titanium alkoxide as the titanium source [10, 11]. The slurry was acetified by HNO3, which became a translucent blue-white liquid with pH between 0.95-0.98. To complete the peptization, the translucent liquid was heated at 80°C in the oil bath for 8 hours under stirring. The resultant suspensions were treated hydrothermally at 200°C for 12 hours. This autoclaving conditions gave rise to average nanoparticles size of 20 nm. The amorphous TiO2 nanoparticles were separated from the solvent by centrifuge.

**Dense nanocrystalline film deposition:** The nanocrystalline TiO2 films were deposited by a spray pyrolysis method using chromatographic atomizer as described earlier [12]. The titanium acetylacetonate (TAA) precursor was prepared by mixing 0.1M of titanium tetra-isopropoxide and 1.2M acetylacetone AcAc in ethanol. The deposited films were annealed at 500°C for 30 min in the air to complete crystallization of TiO2 nanoparticles and to remove the remaining organic traces.

**Nanoporous electrode fabrication and dye absorption:** The pH of the slurry was changed from 2.6 to 5 by adding 0.01M to 0.06M NH4OH to the centrifuged acidic resultant. The TiO2 slurry was carefully stirred and immediately printed by doctor-blade technique on the

substrates covered with the TiO₂ nanocrystalline dense films. After letting to dry in the air for 1 hour, the films were gradually annealed at 500°C for 15 min. The annealed TiO₂ electrodes were cooled down to room temperature and immersed into 0.5 mM D719 dye (Solaronix) in acetonitrile, tertbuthanol 1:1 v/v solution for 4 days.

**Imaging analysis and characterization:** The crystallinity and the phase composition of the TiO₂ nanocrystalline films were examined with Bruker-D8 X-Ray powder diffractometer using CuKα irradiation. The size of the particles and the morphology of TiO₂ film surface were studied by AFMD3100 Atomic Force Microscope.

The absorption spectra of the multilayer photoelectrodes were investigated with a Varian Cray 50 spectrometer. The current-voltage characteristics of photoelectrodes and solar cells were measured by using Kethley 2440 sourcemeter. An AM 1.5 solar simulator (YSS-50, Yamashita Denso) with a 1000 W Xe lamp was employed as the light source. A calibrated Si cell was used as a reference.

**Solar cell assembly:** The dye-adsorbed TiO₂ photoelectrodes and the Pt counter electrodes were assembled into sandwich-type cells as shows in Fig. 3. A 60μm-thick polyethylene spacer was used to separate the TiO₂ electrode from Pt counter electrode. The space between the electrodes was filled with the redox electrolyte consisting of 0.6 M 1-Butyl-3-methylimidazolium iodide BMPImI (Merck), 0.1M Guanidinium thiocyanate NH₂C(NH)NH₂HSCN, and 0.03M I₂ in acetonitrile and valeronitrile v/v 4:1 with 0.5M 4-tert-butylpyridine TBP.

**Discussion and conclusion:** Dense thin nanocrystalline TiO₂ films usually grow to prevent electrical connection of the liquid I⁻/I₃ redox electrolyte with the n-doped FTO conductive electrode. AFM images reveal that after 5-6 consecutive spraying cycles of the TAA diluted solution on the FTO film, the dense packed layer of TiO₂ nanoparticles fully covers the surface.
of the FTO collapses. Figure 1 shows FTO film surfaces before and after spraying of TAA. The size of TiO$_2$ nanoparticles covering the FTO collapses, shown in Fig. 1b, is seen to be varying 15-30 nm. The average size of nanoparticles in the mesoporous TiO$_2$ films that coats dense TiO$_2$ films is 20 nm (Fig. 1c).

XRD analyses show (Fig. 2) the increase in the anatase peaks for the films fabricated from the discharged nanoparticles, when pH of the colloid was 5. The increased intensity of the peaks can be attributed to the co-orientation of the nanocrystallites in the films annealed at higher temperatures. The transparency of the FTO substrates shown in Fig. 4 (black line), is seen to be a little reduced after covering it with the nanocrystalline TiO$_2$ dense layers (Fig. 4-red line). However, the next deposition of the nanoporous thick TiO$_2$ film on the dense film is seen to restore the transparency (Fig. 4-blue line) of the photoelectrodes. Figure 5 shows the photocurrent-photovoltage dependence of the DSSC based on the nanocrystalline TiO$_2$ film fabricated from the colloid with pH5. The parameters of the cells are: open voltage $V_{oc} = 809$ mV, photocurrent density $J_{sc} = 17$ mA/cm$^2$, fill factor 69% and conversion efficiency $\eta = 9.5\%$, cell area 0.12 cm$^2$ with thicknesses of TiO$_2$ photoelectrode 18 µm.

In conclusion, we successfully fabricated the mesoporous nanocrystalline TiO$_2$ photoelectrodes composited the discharged nanoparticles. Ammonia hydroxide was used for the discharging of TiO$_2$ nanoparticles. ~9.5% high conversion efficiency was achieved based on these TiO$_2$ photoelectrodes, and the nature of the TiO$_2$ nanoparticles in the mesoporous film caused the performance of the DSSC. In addition, this technique simplified the fabrication by avoiding some standard procedures such as adding the binder, treating the nanoporous TiO$_2$ surfaces, and immersing the hot electrodes into the dye.
